Abstract

Thirteen patients, who received parathyroidectomy within 5 years after the initiation of hemodialysis, were discussed on their clinical characteristics and their prognoses. 204 patients received the first parathyroidectomy due to secondary hyperparathyroidism in our department, 13 of which were selected on dialysis duration. 9 patients were female and origin of CRF were analgesics-induced interstitial nephritis in 2 and prune-belly syndrome in 1. There were 2 patients who suffered from renal disease more than 30 years. Concomitant primary hyperparathyroidism was suspected in 1 case. In all cases, PTx achieved adequate control of 2HPT after the operation.
